**Abstract.** In conventional aspect-ratio tokamaks, electron cyclotron (EC) waves can provide local heating and current drive. However, the high- $\beta$  spherical tokamak (ST) plasma conditions cut off propagation of EC waves. The electron Bernstein wave (EBW) does not experience a density cut off and is strongly absorbed and emitted at the EC harmonics, allowing EBWCD to be used in STs for current profile control to increase global stability, as well as possible NTM suppression. A critical challenge is to establish and maintain efficient EBW coupling in these high- $\beta$ , H-mode ST plasmas. EBW emission (EBE) diagnostics and EBE modelling have been employed on NSTX to study oblique EBW to O-mode (B-X-O) coupling and propagation. Initial EBE measurements in H-mode plasmas exhibited strong emission before the L-H transition, but the emission rapidly decayed after the transition. EBE simulations show that collisional damping of the EBW prior to mode conversion (MC) can significantly reduce the measured EBE for  $T_e < 30$  eV, explaining the observations. Lithium evaporation was used to reduce EBW collisional damping near the MC layer. The evaporation rate was increased from 0 to 19 mg/min to reduce the electron density and increase the electron temperature outside the last closed flux surface (LCFS) in an H-mode plasma. With edge conditioning, an increase in  $T_e$  near the fundamental MC layer from 10 eV (no Li) to 20 eV (with Li) was observed. As a result the measured B-X-O transmission efficiency increased from  $< 10\%$  (no Li) to 60% (with Li), consistent with EBE simulations. This work has significant implications for future ST devices that use EBWCD, such as an ST-CTF, if the O-X-B MC layer is shifted outside the plasma to a region where  $T_e < 30$  eV. For these conditions, O-X-B heating and CD may become inefficient due to significant EBW collisional losses. This work has demonstrated that using edge conditioning to raise  $T_e$  outside the LCFS can significantly reduce these losses.

### 1. Introduction

Tokamaks and many other magnetically confined plasma devices have utilized electron cyclotron (EC) waves to provide local electron temperature,  $T_e$ , measurements via EC emission (ECE) [1] as well as for localized heating via electron cyclotron resonance heating (ECRH), and current drive via electron cyclotron current drive (ECCD) [2]. However, high- $\beta$  devices, such as the spherical tokamak (ST) and reverse field pinch, routinely operate at relatively high electron densities,  $n_e$ , compared to the confining magnetic field, such that the plasmas are overdense,  $\omega_{pe} \gg \Omega_{ce}$ , where  $\omega_{pe}$  is the electron plasma frequency and  $\Omega_{ce}$  is the electron cyclotron frequency. In these overdense devices, propagation of EC waves beyond the plasma edge is cutoff, prohibiting the use of ECRH and ECCD. The National Spherical Torus Experiment (NSTX, [3]) routinely studies overdense plasmas with  $n_e$  up to  $10^{20} \text{ m}^{-3}$  and  $B_t < 0.6$  T, so that the first four EC harmonics are overdense. An alternative to ECRH and ECCD for these overdense devices is the electrostatic electron Bernstein wave (EBW) [4]. EBWs do not experience a density cutoff in the plasma, propagate mainly perpendicular to the external magnetic field and are strongly absorbed at and emitted from EC resonances. The EBW can couple to the ordinary (O) or extraordinary (X) electromagnetic modes outside of the overdense region of the plasma. Coupling to the EBW can be achieved through B-X (EBW to X-mode coupling) or B-X-O (EBW to X-mode to O-mode coupling) mode

conversion. The work presented here studied microwave plasma emission via B-X-O coupling on NSTX.

In the B-X-O emission process, an EBW is generated near the location where the wave frequency,  $\omega$ , is equal to a harmonic of the  $\Omega_{ce}$ . The EBW travels radially outward towards the plasma edge, perpendicular to the plasma magnetic field, until it encounters the upper hybrid resonance (UHR) layer where  $\omega = \omega_{UHR} = ((\omega_{pe})^2 + (\Omega_{ce})^2)^{1/2}$ . At this point, the perpendicular wave number,  $k_{\perp}$ , of the EBW and slow X-mode branch are equal and full conversion between the two branches occurs. The converted slow X-mode propagates back into the plasma until it encounters the left-hand cutoff of the X-mode. For particular viewing angles, the left-hand cutoff of the slow X-mode branch is coincident with the O-mode cutoff ( $\omega = \omega_{pe}$ ) and the power in the slow X-mode can be transferred efficiently to the O-mode branch. The O-mode then propagates out of the plasma and can be detected by a receiving antenna with an oblique view of the plasma. The transmission window for this process is given by [5]:

$$T(n_{\parallel}, n_{\perp}) = \exp\left\{-\pi k_o L_n \sqrt{\frac{Y}{2}} \left[2(1+Y)(n_{\parallel, opt} - n_{\parallel})^2 + n_y^2\right]\right\} \quad (1)$$

$$Y = \frac{\Omega_{ce}}{\omega} \quad (2)$$

$$n_{\parallel, opt}^2 = \frac{Y}{1+Y} \quad (3)$$

In equation (1) above,  $n_{\parallel}$  and  $n_{\perp}$  are the parallel and perpendicular wave numbers, respectively,  $k_o$  is the vacuum wavelength, and  $L_n$  is the density scale length.  $L_n$  at the mode conversion (MC) location determines the angular width of the window. By decreasing  $L_n$ , the angular width of the window is increased. The center of the B-X-O transmission window in poloidal and toroidal angle depends on the magnetic field and its pitch angle at the MC layer. The B-X-O transmission efficiency in equation (1) only calculates the transmission at the O-mode cutoff layer and does not account for re-absorption and re-emission prior to conversion. An EBW emission (EBE) simulation code was used to calculate these losses.

The inverse process of O-X-B mode conversion can be used to inject power into the plasma to provide localized heating and current drive (CD). The physics of B-X-O emission and O-X-B injection are essentially the same except that the introduction of radiofrequency power may excite lossy nonlinear effects such as parametric decay. Therefore, studying B-X-O emission can be used to assess the feasibility of O-X-B coupling. Modeling has shown that adding 1 MA of off-axis EBW current drive (EBWCD) to an ST Component Test Facility (ST-CTF) plasma significantly increases plasma stability [6] and that efficient Ohkawa EBWCD can be driven well off axis [7]. However, a critical challenge for EBWCD for the ST-CTF is to establish and maintain efficient antenna coupling to the EBW in the plasma during High confinement (H-mode) operation.

This paper presents details of EBE measurements made via B-X-O coupling during NSTX H-mode plasmas. Section 2 describes the NSTX B-X-O emission diagnostic and the EBE simulation code used to model plasma emission. Section 3 presents the EBE measurements obtained during H-mode experiments. Early low emission results (Section 3.1) were determined to be caused by collisional damping of the EBW prior to mode conversion. Edge conditioning was employed to significantly increase the EBE levels (Section 3.2) allowing for

an experimental mapping of the B-X-O transmission window to be performed (Section 3.3). Section 4 summarizes the conclusions.

## 2. Experimental setup and tools

The EBE diagnostic on NSTX consists of two remotely-steered, quadridged microwave antennas [8, 9]. The antennas are located outside of the vacuum vessel, 50 cm from the plasma edge, and have an oblique view of the plasma so the diagnostic is optimized to measure B-X-O emission. The quadridged antennas allow for a simultaneous measurement of the radiation temperature,  $T_{\text{rad}}$ , parallel (O-mode component) and perpendicular (X-mode component) to the plasma's magnetic field when the magnetic field pitch at the MC layer is between  $30^\circ$  and  $45^\circ$ . The ratio of parallel to perpendicular components yields the polarization of the incoming radiation while the sum provides the total  $T_{\text{rad}}$ . The system measures fundamental, second and third harmonic emission ranging from 8-36 GHz. Each antenna mount has two linear actuators that provide movement in the poloidal and toroidal directions between discharges, this feature allows for detailed measurements of the B-X-O transmission window. Each antenna is coupled to a dual-channel, absolutely calibrated, heterodyne radiometer system. The local oscillator for each radiometer is swept at a rate of 10 kHz to provide emission profile measurements. Results presented in this paper are from the 18-36 GHz frequency range. The optical depth for EBWs at low EC harmonic resonances is  $\sim 3000$  in NSTX [10], well satisfying the blackbody condition of  $\tau > 2$ , so the measured  $T_{\text{rad}}$  can be assumed to be equal to the local  $T_e$  provided the B-X-O transmission efficiency is  $\sim 100\%$ . For cases such that the transmission is less than 100%, EBE simulations were used to deduce the transmission efficiency.

The EBE measurements were simulated with a numerical code developed by Preinhaelter et al. [11]. The code simulates the process of O-X-B injection; however, due to the reciprocity of the injection and emission processes [12], the absorption and emission locations equivalent. A bundle of 41 rays are launched in the code to simulate the measured antenna pattern of the EBE diagnostic. A full-wave code [13] calculates the transmission efficiency of the O-X-B mode conversion assuming a 1-D plasma slab model. A 3-D ray-tracing code calculates the propagation and absorption of the EBW after it has mode converted. The inputs for the EBE code are the  $T_e$  and  $n_e$  profiles measured by laser Thomson scattering [14] and the magnetic equilibrium reconstructed by EFIT [15]. Collisions between electrons and ions are incorporated into the EBE code with a Bhatnagar-Krook-Gross collision operator [16, 17]. The simulations neglect the effects of electron-electron collisions due to conservation of momentum while electron-neutral collisions are discarded because the neutral density is less than 5% of the  $n_e$  in the vicinity of the MC layer in NSTX plasmas.

## 3. Experimental Results

Good O-X-B coupling in H-mode plasmas is especially important for future STs that will routinely operate in H-mode regimes and require non-inductive EBWCD or localized EBW heating (EBWH). Recent EBE measurements on NSTX have investigated B-X-O coupling in H-mode plasmas to assess the feasibility of establishing efficient EBW coupling.

### 3.1. Low H-mode EBE results

Early EBE measurements in NSTX H-mode plasmas revealed very low B-X-O transmission efficiencies of less than 10% during the plasma current flattop. The characteristics of a typical

H-mode plasma in NSTX, with  $I_p$  of 1 MA and central  $n_e$  and  $T_e$  of  $4\text{-}6 \times 10^{13} \text{ cm}^{-3}$  and 0.9 keV, respectively, are shown in figure 1. For these H-mode discharges, the measured B-X-O transmission efficiencies were 20-60% for  $f_{ce}$ ,  $2f_{ce}$  and  $3f_{ce}$  (18-36 GHz) emission during the L-H transition. However, during the H-mode phase the measured  $T_{rad}$  was less than 10 eV for all measured harmonics. The emission location for second harmonic (24 GHz) emission (figure 1) remained at a constant major radius of 1 m throughout the discharge.

FIG. 1. (top) The  $I_p$  and central  $T_e$  are shown as a function of time for an H-mode discharge. (bottom) The time evolution of second harmonic emission at 24 GHz is shown for an H-mode discharge. The shaded region represents the uncertainty in the measured  $T_{rad}$ .

Preinhaelter et al. [11] suggested that the observed decay in EBE could be due to collisional damping of the EBW prior to mode-conversion to the slow X-mode if the electron-ion collision frequency,  $\nu_{ei}$ , is greater than  $10^{-4}\omega$ , which typically corresponds to  $T_e < 20$  to 30 eV at the MC layer for NSTX plasmas. For times prior to  $t = 0.25$  s, for the discharge shown in figure 1, the B-X-O MC layer is located within 1 cm of the last closed flux surface (LCFS). For times greater than 0.25 s, the MC layer is shifted 3 to 9 centimeters outside of the LCFS where  $T_e$  is lower than 10 eV. EBE simulations of this plasma without incorporating any effects of collisional damping prior to MC (top solid line in figure 2) predict  $T_{rad} \sim 0.8$  keV, significantly higher than the measured  $T_{rad}$  (bottom solid line in figure 2) which was  $< 20$  eV. When EBW collisional damping prior to MC is included, EBE simulations using from the CHarge Exchange and Recombination Spectroscopy (CHERS) diagnostic on NSTX [18] predict the rapid decay in  $T_{rad}$  observed in the experiment (dashed line in figure 2), but they do not reproduce the observed low  $T_{rad}$  values.

In the simulation shown in figure 2,  $Z_{eff} = 2$ , which was the closest  $Z_{eff}$  measurement available from the CHERS (located 5 cm inboard from the MC layer). The  $Z_{eff}$  measurement from CHERS is calculated based upon the line emission from plasmas where the sole impurity is assumed to be carbon. For many of these plasmas, other impurities are present. EBE simulations with  $Z_{eff}$  of 3-4 predict  $T_{rad}$  levels during the H-mode phase that agree more closely with the measured results (figure 3).

FIG. 2. EBE simulations of the low emission H-mode data, with (dashed line) and without (solid line) collisional damping effects. The error bars represent the uncertainty in the simulations due to errors in  $n_e$  and  $T_e$  from Thomson scattering as well as the magnetic equilibrium reconstruction.

FIG. 3. EBE simulations of the low emission H-mode data with collisional effects, assuming  $Z_{\text{eff}} = 4$ .

The results of these early H-mode experiments and simulations suggest that by decreasing the collisionality at the MC layer, significant improvements in the power coupled from the EBW to slow X-mode branch may be achieved. Since  $\nu_{ei} \propto n_e T_e^{-1/2}$ , either the density can be decreased or  $T_e$  increased to reduce collisional effects. This motivated the need for an edge conditioning tool to decrease  $n_e$  outside the LCFS, which results in shifting the MC layer to a warmer region of the plasma. The next section discusses the method employed for edge conditioning and the resulting effects on the EBE levels.

### 3.2 H-mode EBE results with lithium conditioning

Edge conditioning using lithium (Li) coatings on the plasma facing components has been achieved with a Li evaporation oven (LITER) [19] installed on an upper vacuum vessel port in NSTX. LITER evaporates Li onto the graphite tiles of the centerstack and lower divertor before and during a discharge. The solid Li coating pumps  $D^+$  and  $D^0$  by forming LiD. During a series of EBE experiments to enhance EBW coupling in H-mode discharges, the Li evaporation rate was varied from 0 (i.e., no Li) to 19 mg/min to observe the effect on the EBE  $T_{\text{rad}}$  levels. The parameters for the target H-mode discharge used in this study are shown in figure 4. As a result of Li edge conditioning,  $n_e$  in the plasma scrape off was reduced by nearly a factor of two and consequently the MC layer moved from several centimeters outside the LCFS to the plasma separatrix (figure 5). By moving the MC layer closer to the plasma,  $T_e$  at the fundamental MC layer during the H-mode phase increased from 7 eV (no Li) to nearly 20 eV (with 19 mg/min of evaporated Li).

FIG. 4. The time evolution of (a)  $I_p$ , (b)  $T_e(0)$ , and (c)  $n_e(0)$  are shown for the target H-mode plasmas for the cases with 0 (solid line, no Li) and 19 mg/min (dashed line) of evaporated Li. The L-H transition occurs at 0.145 s.

FIG. 5. The  $n_e$  profile from Thomson scattering is shown as a function of major radius in the plasma scrape off for two cases: without (solid line) and with 19 mg/min (dashed line) of evaporated Li.

FIG. 6. (a) The measured  $T_{rad}$  and (b) B-X-O transmission efficiency are plotted for fundamental EBE (at 18 GHz) for Li evaporation rates of 0 mg/min (solid line) and 19 mg/min (dashed line).

A significant increase in the measured  $T_{\text{rad}}$  from less than 50 eV to greater than 450 eV for  $f_{\text{ce}} = 18\text{GHz}$  (near axis emission) was observed (figure 6 (a)) and agree with the EBE simulated  $T_{\text{rad}}$ . Consequently, the measured B-X-O transmission efficiency was observed to increase from less than 10% (no Li) to 60% (with Li) as shown in figure 6 (b).

The use of Li edge conditioning to increase the B-X-O transmission efficiency allowed for the development of a suitable target plasma to map the angular dependence of the B-X-O transmission efficiency window, shown in equation (1). The next section presents the experimental results from a mapping of the B-X-O transmission window obtained by scanning the EBW antenna viewing direction in the poloidal and toroidal directions.

### 3.3 Experimental mapping of the B-X-O transmission window

A series of target H-mode discharges, with an  $I_p$  of 0.9 MA, central  $T_e \sim 0.8\text{-}0.9$  keV, and  $n_e \sim 3\text{-}5 \times 10^{13} \text{ cm}^{-3}$ , were used for mapping the B-X-O transmission efficiency window. Li was continuously evaporated at a rate of 17 mg/min during each discharge to reduce collisional losses to less than 20%, as indicated by EBE simulations. The target plasma was repeated and the EBE diagnostic antenna was steered to a new viewing direction between discharges. The measured and predicted B-X-O transmission efficiency maps for fundamental (18 GHz) and second harmonic (28 GHz), near axis emission, are shown in figure 7. The maximum measured B-X-O transmission efficiency was  $62 \pm 15\%$  for fundamental and  $48 \pm 15\%$  for second harmonic emission. Good agreement, less than  $5^\circ$ , between the measured and theoretical locations of the optimum angles was observed. The EBE simulation code was also used to determine the poloidal and toroidal angles for optimal transmission, these angles were also within  $5^\circ$  of the measured value. The predicted angle location for optimal EBW transmission from both the theoretical calculations and the EBE simulations are within the  $14^\circ$  acceptance angle of the antenna.

FIG. 7. Experimentally measured B-X-O transmission efficiency map (symbols) in a Li conditioned H-mode plasma for (a)  $f_{\text{ce}} = 18 \text{ GHz}$  and (b)  $2f_{\text{ce}} = 28 \text{ GHz}$ . The contours represent the theoretical B-X-O transmission efficiency (equation 1), where the center represents 90% transmission.

#### 4. Conclusion

Early H-mode experiments revealed very low B-X-O transmission efficiencies, with less than 10% transmission being observed during the  $I_p$  flat-top for the 18-36 GHz EBE frequency range measured. Simulations of these H-mode discharges suggested that the low emission results from significant collisional damping of the EBW prior to mode conversion. These results motivated the need for a tool to reduce the edge collisionality in these plasmas. Lithium evaporation was used to deplete the  $n_e$  in the plasma scrape off layer, moving the MC layer to a region in the plasma where  $T_e \sim 20$  eV. At these temperatures, the collisionality near the MC layer is significantly reduced, which increased the fundamental B-X-O transmission efficiency from 10% to 60%, agreeing with EBE simulation results. Similarly, the second harmonic B-X-O transmission efficiency was increased from 25% to 50%. The increase in EBE during H-mode allowed for an experimental mapping of the B-X-O transmission efficiency to be obtained. The measured, theoretically predicted, and simulated optimum toroidal and poloidal angles for maximum transmission in H-mode plasmas agreed within  $5^\circ$ , verifying that these tools can be used to determine the optimal launch angle and polarization for future EBW heating and CD systems. This work has demonstrated that using edge conditioning to raise  $T_e$  at the MC layer can significantly reduce these losses, providing support for EBW as a viable candidate for localized heating and CD in future ST devices.
